RL = reporting limit, GM = geometric mean, ng/g = nanograms per gram, NA = not applicable (i.e., too few detected results to calculate a GM), ND = not detected, — = PFAS was not measured as part of the study

* This study evaluated dust samples collected from homes, offices, and vehicles in the greater Boston, Massachusetts, area between January and March of 2009. This table presents results for dust samples collected in the main living areas of 30 homes.

⁺ This study evaluated dust samples collected from living rooms and bedrooms from homes in Canada, the Czech Republic, and the United States during the spring and summer of 2013. The results presented in this table are from the 14 homes in the United States.

* As part of this study, dust samples were collected between 2007 and 2009 from carpet or area rugs in the main living areas of homes in California with and without young children residing in the home. This table presents results separately for dust samples collected in the 82 homes with young children and the 42 homes with older adults only.

[§] As part of this study, dust samples were collected between July and September 2010 from 19 homes located in cities with PFAS-contaminated drinking water in Minnesota. Samples were collected at each home from an entryway to the yard as well as in an interior living space (e.g., family room, living room). The results presented in this table are for dust samples collected in interior living spaces only.

Value was less than author-specified method detection limit. For this study, method detection limits varied because they were defined as mean concentration of procedural blanks plus three times the standard deviation of blank response. Values included in this table represent the upper bound of the method detection limit for a given PFAS, unless noted by "ND" (i.e., for PFTrA). For PFTrA, the upper bound method detection limit was greater than the maximum detected value. For PFTrA, the method detection limits ranged from 0.48 to 2.32 ng/g.** Reporting limits for dust not specified in Wu et al. (2015).

Table A2. Comparison values for PFAS measured in blood from other exposure assessments

µg/L = micrograms per liter

* The study reported medians instead of geometric means.

[†] Unadjusted geometric means from the Moose Creek, AK EA are included in this table for comparison.

Appendix B: Additional Background Statistics

As described in the main body of this report, all statistical analyses (e.g., correlations, geometric means, univariate linear regression models, multivariate linear regression models) were completed in SAS version 9.4 (SAS Institute, Cary, NC) following the methods outlined in the study protocol. Several key details on these methods are provided below.

- Consistent with NHANES methodology and per the EA protocol, all non-detect observations were substituted with a value equal to the LOD divided by the square root of 2. Geometric means were not reported for PFAS with 40% or more non-detect observations. Additional information on the effect of this substitution method is provided below.
- Geometric means, 95% confidence intervals around geometric means, and percentiles were calculated with the SURVEYMEANS procedure in SAS. In this procedure, percentiles are based on the population cumulative distribution function.
- Univariate and multivariate regression analyses were conducted with the SURVEYREG procedure in SAS. Multivariate regressions were conducted using a backwards stepwise approach. "Interactions" were only considered when there was a suspected relationship between two variables. Due to the skewed distribution of PFAS blood levels, log transformed (log₁₀) values were used as dependent variables in all linear regression analyses.
- For this EA, all eligible residents within the sampling frame were invited to participate. This means a single household may have multiple participants. To account for the one-stage cluster sampling design used for this EA, household IDs were assigned to each participant. All statistics were calculated while accounting for clustering at the household level by including this household ID variable in a CLUSTER statement in SAS survey procedures. Additional information on the effect of clustering is provided below.
- A finite population correction was applied by including the total number of households in the sampling frame in a TOTAL statement in the SAS survey procedures. For this EA, a total of 317 households were identified within the sampling frame. A finite population correction corrects the standard errors when sampling without replacement from a finite population and is recommended when sample size is greater than 5% of the population being sampled.
- A p-value of less than 0.05 was used to identify statistically significant associations in regression models and 95% confidence limits were provided for all estimated geometric means.
- Age-adjusted statistics were calculated using the POSTSTRATA statement in the PROC SURVEYREG procedure in SAS. For age adjustments to the sampling frame population, the number of people in the sampling frame for each 5-year age interval (5–9 years, 10–15 years, etc.) was calculated from census block data from 2010 and was used as poststratum totals (_PSTOTAL_). Similarly, for age-adjustments to the NHANES population, estimates of the U.S. population in each age category starting from 12–14 years and increasing by 5–year age intervals (15–19 years, etc. through 80+) were calculated.

Additional details on non-detect observations

As noted, all results reported below the LOD were substituted with a value equal to the LOD divided by the square root of 2. For blood, all PFAS and all samples were reported from the laboratory with an LOD of 0.1 μ g/L, and non-detect observations were therefore substituted with a value equal to 0.071 μ g/L. The same method was applied to urine results (LOD=0.1 μ g/L) and dust (LOD varies by PFAS and

sample); only the frequency of detection and range of detected values were computed for tap water for this EA due to low detection frequency.

The study protocol also notes that a sensitivity analysis of aggregate PFAS blood data should be performed using other statistical methods to account for censoring. More specifically, for datasets in which less than 50% of the data are censored (i.e., not detected), the Kaplan–Meier method should be used to calculate summary statistics; and for data sets with between 50% and 80% censored results, maximum likelihood estimation should be used. Only high sample percentiles should be reported for data sets with more than 80% censoring. Given that no nationally representative comparison values using these methods are available, results of this sensitivity analyses should only be used as a comparison to results obtained using the simpler substitution method described above.

Based on these criteria, ATSDR compared geometric means for all PFAS measured in blood (except Sb– PFOA) using the two alternate substitution methods. As shown in Table B1, there is minimal difference in geometric mean estimates when using these methods, and alterative substitution methods would therefore have no effect on the conclusions of this report. This is expected for these data due to the single censoring threshold for all PFAS and blood samples [Helsel 2009].

PFAS	Geometric Mean Calculated with LOD/Square Root of 2 (μg/L)	Geometric Mean Calculated with Kaplan Meier Approach (µg/L)	Geometric Mean Calculated with Maximum Likelihood Estimation (μg/L)
PFHxS	11.65	12.31	12.04
n–PFOS	12.05	12.05	12.06
sm–PFOS	6.07	6.07	6.09
n–PFOA	2.03	2.03	2.03
sb–PFOA	NA*	NA*	NA*
PFNA	0.32	0.33	0.32
PFDA	0.11	0.13	0.10
PFUnA	0.09	0.12	0.08
MeFOSAA	0.14	0.15	0.13

Table B1. Comparison of geometric mean blood levels with various substitution methods

LOD = limit of detection, μ g/L = micrograms per liter, NA = not applicable

* LOD does not meet the threshold set in EA protocol for sensitivity analyses (<20%).

More details on precision and clustering for PFAS blood data

As noted in the study protocol, this investigation was designed to estimate mean concentrations of PFAS in blood for the sampling frame population, with a given level of precision. The target sample size for this EA was based on a desired precision of 15% and 5% level of significance. Table B2 presents the estimated precision for the mean of the log transformed (In) PFAS concentrations measured in serum. This was calculated as the difference between the upper confidence interval of In(PFAS) and the mean In(PFAS), divided by mean In(PFAS). Precision estimates ranged from 10% to 23%. Except for PFHxS and PFOA, these values are all below the desired precision of 15% used to determine the target sample size for this EA. The collected data met the precision target specified in the EA protocol; the precision estimate for PFOS was 11%, which is below the target precision of 15% for the EA. Additional information on target precision is provided in the study protocol.

Note that throughout the main body of the report and Appendix C, geometric means are presented with 95% confidence intervals and regression modeling results are presented with p-values. These statistics provide further insight into the precision of those estimates.

To quantify the effect of clustering and to compare the results of this EA to the assumptions used to determine the target sample size for the EA (listed in the protocol), ATSDR calculated the intra–cluster correlation coefficient (ICC) and design effect for each PFAS that was detected in at least 60% of blood samples (Table B2). ICCs were estimated using variance components from the MIXED procedure in SAS. In brief, a mixed model was run for each PFAS while treating clusters (i.e., households) as a random effect. The ICC was calculated as the ratio of the variance attributable to the random effect (households) divided by the total of the random effect and error variances. The design effect was calculated using the DEFF option in the MODEL statement of the SURVEYREG procedure in SAS. This provides an estimate of the ratio of the actual variance to the variance computed under the assumption of simple random sampling. This information, along with the average number of study participants per house, was then used to calculate the effective sample size for each PFAS. This statistic provides an estimate of the sample size that would be required to achieve the same level of precision if a simple random sample study design was used.

The target sample size for this EA was 395 people, based on (1) an ICC of 0.54 for PFOS calculated from data collected as part of biomonitoring study conducted by the New York State Department of Health and the Pennsylvania Department of Health, (2) a design effect of 2.1, and (3) and effective sample size of 188 people. Refer to the study protocol for more details on how these values were derived.

PFAS	Household ICC (Unitless)	Design Effect (Unitless)	Effective Sample Size (n)	Standard Deviation of In(PFAS) (µg/L)	Precision of Mean In(PFAS) (%)
PFHxS	0.47	1.94	45	2.01	17.1
PFOS	0.51	1.73	51	1.58	11.3
n–PFOS	0.54	1.77	50	1.63	13.7
Sm–PFOS	0.43	1.62	54	1.49	17.2
PFOA	0.45	1.54	57	0.832	23.1
n–PFOA	0.45	1.54	57	0.862	25.4
Sb–PFOA	NA*	NA*	NA*	NA*	NA*
PFNA	0.20	1.25	71	0.704	12.9
PFDA	NA*	NA*	NA*	NA*	NA*
PFUnA	NA*	NA*	NA*	NA*	NA*
MeFOSAA	0.58	1.74	51	0.910	9.6

Table B2. Statistics related to clustering in blood data (all participants)

 μ g/L = micrograms per liter, NA = not applicable

* Per the protocol, geometric means were not calculated for PFAS detected in less than 60% of samples.

Blood ICCs for this EA ranged from 0.20 to 0.58, suggesting weak to moderate correlation. The design effects ranged from 1.25 to 1.94, all of which are lower than the assumed design effect of 2.1. Effective sample size estimates ranged from 45 to 71. For all PFAS, the design effect in this EA is smaller than that assumed in the protocol in part because of a smaller number of people per household. In this EA the average number of people per household was 1.83 (compared to 3.0, assumed in the protocol).

Appendix C: PFAS Blood Levels by Demographics and Exposure Characteristics

This appendix provides geometric mean blood PFAS concentrations and 95% confidence intervals stratified by demographic or exposure characteristics for the five PFAS with detection frequencies above 60% (i.e., PFHxS, PFOS, PFOA, PFNA, and PFDA). Also included are univariate regressions, multivariate regressions, and box and whisker plots. For each regression, the outputs shown are coefficient estimates, p–values, and marginal effects. The coefficient represents the increase in PFAS blood levels (in units of $\log_{10}[\mu g/L]$) per unit increase of the independent variable shown on the left side of the table for continuous variables, or when comparing to the reference category for categorical variables. The p–value indicates the significance of the results. Generally, p–values less than 0.05 indicate significant results. The marginal effect is the percent change in PFAS blood levels (in units of $\mu g/L$) per unit increase of the reference category for categorical variables.

* Several variables that were collected in the questionnaire are not included in these tables. These variables may not be included because they did not have sufficient variability or were not associated with PFAS blood concentrations in preliminary analyses. These variables include full-time vs. part-time residence, consumption of local milk, behavior change questions, and occupational history in specific industries.

⁺ Geometric means and confidence levels are not shown for categories with fewer than 10 responses.

[‡] Detection limits for all PFAS are 0.1 micrograms per liter (μg/L).

[§] Some frequency counts may not sum to the total because of missing values. Some variable categories that were presented in the questionnaire were collapsed into larger variable categories.

* Several variables that were collected in the questionnaire are not included in these tables. These variables may not be included because they did not have sufficient variability or were not associated with PFAS blood concentrations in preliminary analyses. These variables include full-time vs. part-time residence, consumption of local fruits and vegetables, consumption of local fish, consumption of local milk, school attendance, days since water treatment.

⁺ Geometric means and confidence levels are not shown for children for this EA because fewer than 10 children participated (n=9).

* Some frequency counts may not sum to the total because of missing values. Some variable categories that were presented in the questionnaire were collapsed into larger variable categories.

* Not all categorical variables included in Table C1 are included in Table C3: variable categories that had fewer than 10 responses were not included in the regressions (Table C3). These variables include kidney disease history, blood donation frequency, frequency of local fish consumption, frequency of local milk consumption, and biological children (yes/no).

⁺ This marginal effect is interpreted as percent increase in blood PFOA level per percent increase in PFOA well water concentration.
